DEFINITION OF TERMS

BASE FLOW: Sustained or fair weather flow of a stream.

BED MATERIAL: The sediment mixture of which the streambed is composed.

CROSS SECTION: A line across a stream along which one or more samples or measurements are taken.

DRAINAGE AREA: The area, measured in a horizontal plane, enclosed by a topographical divide from which direct surface runoff from precipitation normally drains into a stream above a specified point on a stream.

EDI: Centroid-of-equal-discharge-increment method of stream sampling.

Depth integrated samples are taken in the center of a number of stream sections in the cross section, with each section representing an equal amount of water discharge.

EWI: Equal-width-increment method of stream sampling. Depth integrated samples are taken in the center of a number of increments in the cross section, with each increment having an equal width.

EROSION: The detachment and movement of soil and rock particles by hydrologic and geologic processes.

PARTICLE-SIZE CLASSIFICATION OF SEDIMENT:

Class name:	Size (mm)
Clay	0.00024 - 0.004
Silt	.004 - .062
Sand	.062 - 2.0
Gravel	2.0 - 64.0

PEAK FLOW: Maximum streamflow occurring during a specified time period.

RUNOFF: That part of precipitation that appears in surface streams.

SUSPENDED-SEDIMENT CONCENTRATION: The concentration by weight of sediment that is carried in suspension by the turbulent components of the fluid or by Brownian movement.

SUSPENDED-SEDIMENT DISCHARGE: The rate at which suspended sediment passes a section of a stream, expressed as the dry weight of sediment discharged in a given time, as in tons per day.

WATER DISCHARGE: The rate at which water passes a section of a stream, expressed as the volume of water discharged in a given time, as in cubic feet per second.

WATER DISCHARGE HYDROGRAPH: A graph showing the variation of water discharge with respect to time.

WATER STAGE: The height of a stream surface above an established datum.

WATER YEAR: October 1 to September 30.

SEDIMENT DATA FOR GEORGIA STREAMS, WATER YEARS 1958-82

By Howard A. Perlman

ABSTRACT

Sediment data have been collected regularly in Georgia by the U.S. Geological Survey since 1957. The data were collected in cooperation with a number of State and Federal agencies. The frequency of data collection varied and several sampling methodologies were used.

This report presents suspended-sediment-concentration data for 179 sites, suspended-sediment particle-size data for 16 sites, and bed-material particle-size data for 19 sites, collected from October 1957 to September 1982.

INTRODUCTION

The U.S. Geological Survey began collecting sediment data in Georgia in 1957. Before 1957, occasional sampling was done by various State and Federal agencies for reservoir planning and construction and for other purposes. The reader is referred to Harris (1962) for more information about these data.

From 1957 to the midsixties, a few stations were operated intermittently as daily or weekly sampling sites, and numerous other stations were sampled periodically. From the midsixties to the early seventies, fewer streams were sampled, mainly on a periodic basis. During 1957-76, 30 sites were sampled as part of the river-quality assessment of the upper Chattahoochee River basin. Since the late sixties, three National Stream-Quality Accounting Network (NASQAN) sites have been sampled bimonthly and one hydrologic bench-mark site has been sampled monthly. Since the midseventies, 14 other sites have been sampled about every 6 weeks under a reconnaissance program in cooperation with the Georgia Environmental Protection Division. Sediment data were collected periodically and during storm events in 1981 and 1982 at five sites in cooperation with the U.S. Army Corps of Engineers.

Purpose and Scope

The purpose of this report is to present suspended-sediment and bed-material data collected by the U.S. Geological Survey in Georgia for the 1958-82 water years. Tables in the report show suspended-sediment data for 179 sites, suspended-sediment particle-size data for 16 sites, and bed-material particle-size data for 19 sites.

Previous Studies

Kennedy (1964) published a compilation of Georgia sediment data collected at 33 stations from December 1957 to June 1959. Included in that report is a list of stations where data were collected prior to December 1957, but not published. Faye and others (1980) presented sediment data collected during 1975-76 for the upper Chattahoochee River basin study. Periodic sediment data for some Georgia streams are published annually (U.S. Geological Survey, 1976-82).

Cooperation and Acknowledgments

The U.S. Geological Survey has collected and continues to collect sediment data for a number of purposes and in cooperation with several State and Federal agencies.

Much of the planning for this report, along with the initial data organization and editing, was performed by William P. Carey, U.S. Geological Survey. His work is gratefully acknowledged.

FACTORS DETERMINING SEDIMENT CHARACTERISTICS OF A STREAM

Sediment characteristics of a stream are constantly changing and are generally dependent on the nature of the soil in the drainage basin, the ability of the erosion process to transport soil and other material into the stream, and the ability of the stream to move sediment in suspension and along the streambed. A number of interrelated factors determine the type of sediment available for transport and the sediment-carrying capacities of Georgia streams.

Soil

The characteristics of the soil in a drainage basin are a factor in determining the type and amount of sediment entering a stream. Fine-grained soils, such as silt and clay, are subject to surface sealing which reduces infiltration and increases surface runoff. When eroded, these soils are readily suspended and transported, even in slow-moving water. Sandy soils rapidly absorb rainfall and reduce surface runoff, and require more energy to be transported into and carried by a stream.

Soil characteristics vary in the different physiographic provinces of Georgia. (See pl. 1 for delineation of physiographic provinces.) Sandy soils predominate in the Coastal Plain province, whereas finer grained soils, ranging from sandy loam to clay loam, are dominant in the Piedmont province. Soils in the Blue Ridge, Valley and Ridge, and Cumberland Plateau provinces of north Georgia are also relatively fine grained, and consist mainly of clay loams, silt loams, and sandy loams.

Relief

The sediment transport characteristics of a stream are also influenced by the relief in the drainage basin. In areas of high relief and steep slopes, surface runoff is generally more erosive than runoff in areas of low relief. Streams in areas of high relief generally have steep gradients and high water velocities, and are capable of transporting large quantities of sediment in a wide range of grain sizes.

Large differences in relief are evident among the physiographic provinces of Georgia. The Coastal Plain is comparatively flat and has little relief. The Piedmont province, which is dominated by rolling hills and is marked by isolated mountains in the northern part, has low to moderate relief. The Valley and Ridge province in northwestern Georgia consists mainly of gently sloping valleys separated by steep, level-top ridges. Although the altitude differences between the ridge crests and the valley floors are large, most of the erodible land lies on the valley floors where channel slopes are not steep. Thus the high relief in this area does not produce the energy needed to transport large amounts of sediment (Kennedy, 1964). The Cumberland Plateau includes deep, narrow valleys, but most of the area is a hilly upland of low to moderate relief. The Blue Ridge province in northern Georgia has much higher relief than the rest of the State. The area contains the highest mountains in Georgia and is characterized by deep, narrow stream valleys. Streams in this province generally have steeper gradients and higher velocities than streams in other areas of the State. Relief is a major factor in sediment transport in the Blue Ridge province (Kennedy, 1964).

Land Use and Land Cover

Land use and land cover significantly affect the sediment characteristics of streams. Soil erosion on forested land and in areas having thick ground cover is generally minimal. Erosion on land that has been stripped of its vegetative cover and left unprotected commonly is very active. Farm-land located in stream valleys is a primary source of erodible soil, especially when the land is bare before spring planting and after harvesting. In such areas, suspended-sediment concentration can vary significantly with the time of year.

Georgia has experienced severe erosion problems owing to improper land-use practices. Trimble (1969) describes the drastic changes that occurred in the river valleys of the mid-Piedmont between about 1850 and 1930. The clearing of forests, increased use of row-crop farming methods, and lack of soil conservation practices led to extensive erosion and to the burying of much productive river-bottom land. Soil conservation measures that began in the thirties have greatly reduced soil erosion throughout the State, and some previously buried river valleys have begun to clear themselves of accumulated sediment.

Urbanization and construction can subject land to erosion and result in the transport of large quantities of previously stable soil. Wolman and Schick (1967) demonstrated that maximum suspended-sediment concentrations

could increase by as much as 75 times normal during urbanization, and Reed (1980) noted a twofold to fourfold increase in suspended-sediment discharge during highway construction. According to Reed, these increases generally were temporary during the disturbance of the land, and after construction sediment transport quickly returned to preconstruction levels.

Control Structures

Control structures, such as dams and farm ponds, effectively trap a large amount of sediment. Kennedy (1964) stated that the trap efficiency of most large reservoirs in Georgia is probably between about 81 and 98 percent, and Flint (1971) computed an 85-percent trap efficiency for a small reservoir in northwest Georgia. Because most of the large streams, especially those north of the Fall Line, have been dammed, it is probable that much of the sediment eroded from Georgia's drainage basins is trapped and deposited in reservoirs. Kennedy (1964) also noted that farm ponds do not trap as much sediment as large reservoirs because they intercept only a small proportion of surface runoff.

Rainfall and Storms

The type and intensity of rainfall are extremely important in determining the sediment characteristics of a stream. Precipitation runoff is the principal source of the energy needed to move soil into a stream and it directly provides almost all of the water in a stream during runoff. Rainfall in Georgia varies according to time of year. Summertime rain generally is in the form of high-intensity convective showers of short duration, and rainfall commonly is limited to small parts of a drainage basin. These intensive storms can be highly erosive, but because of their localized nature and short duration, they generally do not produce high water and sediment discharges. Extended rainfall that produces a large amount of runoff over a broad area occurs mainly in the winter and early spring. During this time of year, high water and sediment discharges can be maintained for long periods, depending on basin size and relief. For this reason, much of the sediment discharge during a year at a typical Georgia sediment station can occur during one or a few large storms. Kennedy (1964) estimated that during the 1959 water year at the Etowah River near Canton station, about 75 percent of the annual suspended-sediment load was carried during about 10 percent of the time.

Storm activity, especially in small drainage basins, produces a characteristic type of suspended-sediment-concentration curve that clearly shows the relation of rainfall to suspended-sediment discharge. A flush of sediment into the stream generally occurs in the first hours of the storm cycle, and the suspended-sediment concentration can rise dramatically during this period. The concentration generally continues to rise as flow increases, but the concentration curve tends to peak before the flow peaks. Then, as flow diminishes, the suspended-sediment concentration tends to diminish at an even faster rate and can return to base-flow values even though the streamflow may not return to base-flow conditions for days.

If another significant amount of precipitation occurs before the discharge hydrograph has returned to base flow, the suspended-sediment concentration may again rise dramatically. However, the concentration may not peak as high as during the first storm, even though the peak flow for the second storm is higher. This is because much of the easily erodible soil was washed into the stream during the first storm. An event of this type is illustrated by the data for the storms of February 16-19, 1964, at Broad River near Bell (station number 02192000, table 2).

Streams in the various physiographic provinces of Georgia react differently to storm rainfall. Streams in the northern provinces (pl. 1) especially those having small drainage basins, react rapidly to storm precipitation in the manner described above. Streams in the Coastal Plain react much more slowly to storm rainfall, and the discharge hydrographs rise and fall gently over several days. The low relief of this area keeps water velocities low even when flow has increased. Suspended-sediment concentrations in Coastal Plain streams increase only slightly during an increase in water discharge because the permeable soil and low relief do not promote surface runoff. In this region, sediment discharge rises and falls simultaneously with water discharge.

METHODS OF DATA COLLECTION AND ANALYSIS

Suspended-sediment-concentration data have been collected by a variety of sampling techniques. Before the midsixties, most sediment samples were collected by local resident observers hired by the U.S. Geological Survey. Single-bottle samples were collected by the observers at either the midpoint of the stream or at a point presumed to yield a concentration approximately equal to the cross-sectional mean. U.S. Geological Survey personnel also collected cross-section samples at these sites, but less frequently.

After the midsixties, most sediment samples were collected by U.S. Geological Survey personnel. Samples were collected at a number of points across the streams rather than only at a single point. Standard methods of sampling, such as the equal-width-increment (EWI) and equal-discharge-increment (EDI), were used, and quality-control measures such as duplicate sampling and careful visual inspection of samples were implemented. The EWI and EDI sampling methods and sediment-sampler descriptions are given by Guy and Norman (1970).

Determinations of suspended-sediment concentrations and particle-size distributions prior to 1968 were made in the U.S. Geological Survey laboratories at Ocala, Fla., and Raleigh, N.C., and after 1967 at the Harrisburg, Pa., sediment laboratory. Laboratory methods of sediment analyses are described by Guy (1969).

DATA COMPILATION AND ORGANIZATION

The different sediment-sampling techniques were considered in the compilation and organization of the data. The suspended-sediment concentration at single-bottle sample sites is simply reported as the individual value. The

suspended-sediment concentration at multibottle sites for samples collected prior to 1978 is a composited value computed from the individual samples taken at various intervals across the stream and represents a volume-weighted average of all concentrations in the cross section. Volume-weighted average concentrations were computed from samples collected before 1978 because samples were collected either by (1) sampling at two or more equal intervals across the stream, (2) sampling with the EWI method, or (3) sampling in an unknown manner. After 1977, samples were generally collected by the EDI sampling method, where samples are collected at three or more points across the stream, each point being approximately at the midpoint of a section that represents equal water discharge. The concentration value reported for multibottle samples collected after 1977 is a simple average of the cross-sectional concentrations.

The particle size of suspended sediment was determined on composited samples except when cross-sectional variations of particle size were being investigated. Particle size of bed material was determined and reported for individual samples.

COMPUTATION OF WATER DISCHARGE

To properly evaluate suspended-sediment data and to compute suspended-sediment discharge requires a corresponding water-discharge value for every cross-sectional mean suspended-sediment concentration value. Most concentration values listed in this report have a corresponding water-discharge value. These values were available from a water-discharge measurement performed at the time of sampling, or were obtained from an appropriate stage-discharge relation. Many of the corresponding water discharges for samples collected before about 1965 are estimated. These were made by estimating the gage height at the time of sampling and then determining the water discharge from a gage height-water discharge relation computed from a number of earlier water-discharge measurements. Some sediment-sampling stations had no stage recorders or had stage records for too short a time to develop a gage height-water discharge relation. Water-discharge values could not be estimated at these stations, and a dash appears in the water-discharge column of the data table.

DATA EDITING

All suspended-sediment concentrations were carefully checked using a number of procedures to insure that the values represented the stream conditions at the time of sampling. When a concentration was judged to be unrepresentative, it was deleted from the original data set. The decision to keep or delete a sediment concentration value was based on (1) the relations between suspended-sediment concentration and water discharge, and (2) notes on the field work sheets at the time of sample collection and on laboratory work sheets at the time of sample analysis.

The relation between suspended-sediment concentration and water discharge was examined for sites having more than about 15 samples. Suspended-

sediment concentrations and corresponding water discharges were plotted by a desktop computer to enable visual inspection of the relation. This procedure revealed some data points that plotted outside the pattern established by most data values. Least-squares regression lines then were drawn, and regression statistics were calculated. Where possible, the data were plotted and statistics calculated according to (1) a specified season or period of months, (2) specified ranges of water discharge, (3) a specified period of years, or (4) rising, falling, and steady stages. These plots provided information on questionable values that were then deleted if judged to be erroneous.

The suspended-sediment concentration and water-discharge hydrographs were examined for storms at stations where enough data were available. Suspended-sediment-concentration data collected during storms were plotted against time and compared to the discharge hydrograph to see if they followed a typical storm pattern. Concentrations that deviated substantially from a typical storm pattern were deleted.

Some suspended-sediment concentrations were higher than would be expected for the water discharge at the sampling time. The concentrations may have resulted from improper sampling. Many sampling errors result from the nozzle of the sampler hitting the streambed or remaining too long near the stream bottom where sediment concentration is highest. Unexpectedly high concentrations were closely reviewed and, when justified, were deleted from the original data set. High values were generally deleted if the corresponding water discharge was at or near base flow, a time when concentrations are relatively low.

The laboratory work sheets for each sediment analysis were used as part of the editing procedure. Samples that were noted by the laboratory analyst as having a large amount of sand, especially if water discharge was low, or as having a low water volume, were marked for further investigation. Field notes made during sample collections were also checked for indications of sampling problems.

More error can be expected in samples collected by observers in the late fifties and sixties than in samples collected during the seventies and eighties, when U.S. Geological Survey personnel used EWI and EDI sampling procedures. Therefore, deletion of data collected prior to about 1970 was more common than for data collected afterward.

DATA PRESENTATION

Georgia sediment stations are listed in table 1 by U.S. Geological Survey downstream order number. The map identification number, number of samples, minimum and maximum water discharges (where available), and minimum and maximum suspended-sediment concentrations for the data of each station are also shown. The station locations, major river basin boundaries, and the physiographic provinces of Georgia are shown on plate 1.

There are three data tables that are also arranged according to downstream order number. Table 1 presents suspended-sediment concentrations and

related information, along with the corresponding percentage of silt plus clay (where available) for 179 stations. Table 2 shows suspended-sediment particle-size data for 16 stations, and table 3 shows bed-material particle-size data for 19 stations.
